

## MEMBRANE PROBING SYSTEM

## BACKGROUND OF THE INVENTION

The present invention relates to probe  
5 assemblies of the type commonly used for testing  
integrated circuits (IC) and, in particular, the present  
invention relates to a membrane probing assembly having  
contacts which scrub, in a locally controlled manner,  
10 across the respective input/output conductors of each  
device so as to reliably wipe clear the surface oxides  
that are normally found on those conductors thereby  
ensuring good electrical connection between the probing  
assembly and each device.

The trend in electronic production has been  
15 toward increasingly smaller geometries particularly in  
integrated circuit technology wherein a very large number  
of discrete circuit elements are fabricated on a single  
substrate or "wafer." After fabrication, this wafer is  
divided into a number of rectangular-shaped chips or  
20 "dice" where each die presents a rectangular or other  
regular arrangement of metallized contact pads through  
which input/output connections are made. Although each  
die is eventually packaged separately, for efficiency  
sake, testing of the circuit formed on each die is pref-  
25 erably performed while the dies are still joined together  
on the wafer. One typical procedure is to support the  
wafer on a flat stage or "chuck" and to move the wafer in  
X, Y and Z directions relative to the head of the probing  
assembly so that the contacts on the probing assembly  
30 move from die to die for consecutive engagement with each  
die. Respective signal, power and ground lines are run  
to the probing assembly from the test instrumentation  
thus enabling each circuit to be sequentially connected  
to the test instrumentation.

35 One conventional type of probing assembly used  
for testing integrated circuits provides contacts that  
are configured as needle-like tips. These tips are

mounted about a central opening formed in a probe card so as to radially converge inwardly and downwardly through the opening. When the wafer is raised beyond that point where the pads on the wafer first come into contact with these tips, the tips flex upwardly so as to skate forwardly across their respective pads thereby removing oxide buildup on the pads.

The problem with this type of probing assembly is that the needle-like tips, due to their narrow geometry, exhibit high inductance so that signal distortion is large in high frequency measurements made through these tips. Also, these tips can act in the manner of a planing tool as they wipe across their respective pads, thereby leading to excessive pad damage. This problem is magnified to the extent that the probe tips bend out of shape during use or otherwise fail to terminate in a common plane which causes the more forward ones of the tips to bear down too heavily on their respective pads. Also, it is impractical to mount these tips at less than 100 micron center-to-center spacing or in a multi-row grid-like pattern so as to accommodate the pad arrangement of more modern, higher density dies. Also, this type of probing assembly has a scrub length of the needle tips of 25 microns or more, which increases the difficulty of staying within the allowed probing area.

In order to reduce inductive losses, decrease pad wear and accommodate smaller device geometries, a second type of probing assembly has been developed that uses a flexible membrane structure for supporting the probing contacts. In this assembly, lead lines of well-defined geometry are formed on one or more plies of flexible insulative film, such as polyimide or MYLAR™. If separate plies are used, these plies are bonded together to form, for example, a multilayered transmission line structure. In the central portion of this flexible structure or membrane, each conductive line is terminated

by a respective probing contact which is formed on, and projects outwardly from, an outer face of the membrane. These probing contacts are arranged in a predetermined pattern that matches the pattern of the device pads and typically are formed as upraised bumps for probing the flat surfaces conventionally defined by the pads. The inner face of the membrane is supported on a supporting structure. This structure can take the form, for example, of a truncated pyramid, in which case the inner face of the center portion of the membrane is supported on the truncated end of the support while the marginal portions of the membrane are drawn away from the center portion at an angle thereto so as to clear any upright components that may surround the pads on the device.

With respect to the membrane probing assembly just described, excessive line inductance is eliminated by carefully selecting the geometry of the lead lines, and a photolithographic process is preferably used to enable some control over the size, spacing, and arrangement, of the probing contacts so as to accommodate higher density configurations. However, although several different forms of this probing assembly have been proposed, difficulties have been encountered in connection with this type of assembly in reducing pad wear and in achieving reliable clearing of the oxide layer from each of the device pads so as to ensure adequate electrical connection between the assembly and the device-under-test.

One conventional form of membrane probing assembly, for example, is exemplified by the device shown in Rath European Patent Pub. No. 259,163A2. This device has the central portion of the sheet-like membrane mounted directly against a rigid support. This rigid support, in turn, is connected by a resilient member comprising an elastomeric or rubber block to the main body of the assembly so that the membrane can tilt to match the tilt of the device. Huff U.S. Patent No.

4,918,383 shows a closely related device wherein radially extending leaf springs permit vertical axis movement of the rigid support while preventing it from tilting so that there is no slippage or "misalignment" of the contact bumps on the pads and further so that the entire membrane will shift slightly in the horizontal plane to allow the contacts to "scrub" across their respective pads in order to clear surface oxides from these pads.

In respect to both of these devices, however, because of manufacturing tolerances, certain of the contact bumps are likely to be in a recessed position relative to their neighbors and these recessed bumps will not have a satisfactory opportunity to engage their pads since they will be drawn away from their pads by the action of their neighbors on the rigid support. Furthermore, even when "scrub" movement is provided in the manner of Huff, the contacts will tend to frictionally cling to the device as they perform the scrubbing movement, that is, there will be a tendency for the pads of the device to move in unison with the contacts so as to negate the effect of the contact movement. Whether any scrubbing action actually occurs depends on how far the pads can move, which depends, in turn, on the degree of lateral play that exists as a result of normal tolerance between the respective bearing surfaces of the probe head and chuck. Hence this form of membrane probing assembly does not ensure reliable electrical connection between each contact and pad.

A second conventional form of membrane probing assembly is exemplified by the device shown in Barsotti. European Patent Pub. No. 304,868A2. This device provides a flexible backing for the central or contact-carrying portion of the flexible membrane. In Barsotti, the membrane is directly backed by an elastomeric member and this member, in turn, is backed by a rigid support so that minor height variations between the contacts or pads can be accommodated. It is also possible to use

positive-pressure air, negative-pressure air, liquid or an unbacked elastomer to provide flexible backing for the membrane, as shown in Gangroth U.S. Patent No. 4,649,339, Ardezzone U.S. Patent No. 4,636,772, Reed, Jr. et al. U.S. Patent No. 3,596,228 and Okubo et al. U.S. Patent No. 5,134,365, respectively. These alternative devices, however, do not afford sufficient pressure between the probing contacts and the device pads to reliably penetrate the oxides that form on the pad surfaces.

10 In this second form of membrane probing assembly, as indicated in Okubo, the contacts may be limited to movement along the Z-axis in order to prevent slippage and resulting misalignment between the contacts and pads during engagement. Thus, in Barsotti, the rigid support underlying the elastomeric member is fixed in position although it is also possible to mount the support for Z-axis movement in the manner shown in Huff U.S. Patent No. 4,980,637. Pad damage is likely to occur with this type of design, however, because a certain amount of tilt is typically present between the contacts and the device, and those contacts angled closest to the device will ordinarily develop much higher contact pressures than those which are angled away. The same problem arises with the related assembly shown in European Patent Pub. No. 230,348A2 to Garretson, even though in the Garretson device the characteristic of the elastomeric member is such as to urge the contacts into lateral movement when those contacts are placed into pressing engagement with their pads. Yet another related assembly is shown in Evans U.S. Patent No. 4,975,638 which uses a pivotably mounted support for backing the elastomeric member so as to accommodate tilt between the contacts and the device. However, the Evans device is subject to the friction clinging problem already described insofar as the pads of the device are likely to cling to the contacts as the support pivots and causes the contacts to shift laterally.

Yet other forms of conventional membrane probing assemblies are shown in Crumly U.S. Patent No. 5,395,253, Barsotti et al. U.S. Patent No. 5,059,898 and Evans et al. U.S. Patent No. 4,975,638. In Crumly, the center portion of a stretchable membrane is resiliently biased to a fully stretched condition using a spring. When the contacts engage their respective pads, the stretched center portion retracts against the spring to a partially relaxed condition so as to draw the contacts in radial scrub directions toward the center of the membrane. In Barsotti, each row of contacts is supported by the end of a respective L-shaped arm so that when the contacts in a row engage their respective pads, the corresponding arm flexes upwardly and causes the row of contacts to laterally scrub simultaneously across their respective pads. In both Crumly and Barsotti, however, if any tilt is present between the contacts and the device at the time of engagement, this tilt will cause the contacts angled closest to the device to scrub further than those angled further away. Moreover, the shorter contacts will be forced to move in their scrub directions before they have had the opportunity to engage their respective pads due to the controlling scrub action of their neighboring contacts. A further disadvantage of the Crumly device, in particular, is that the contacts nearer to the center of the membrane will scrub less than those nearer to the periphery so that scrub effectiveness will vary with contact position.

In Evans et al. U.S. Patent No. 5,355,079 each contact constitutes a spring metal finger, and each finger is mounted so as to extend in a cantilevered manner away from the underlying membrane at a predetermined angle relative to the membrane. A similar configuration is shown in Higgins U.S. Patent No. 5,521,518. It is difficult, however, to originally position these fingers so that they all terminate in a common plane, particularly if a high density pattern is required.

Moreover, these fingers are easily bent out of position during use and cannot easily be rebent back to their original position. Hence, certain ones of the fingers are likely to touch down before other ones of the fingers, and scrub pressures and distances are likely to be different for different fingers. Nor, in Evans at least, is there an adequate mechanism for tolerating a minor degree of tilt between the fingers and pads. Although Evans suggests roughening the surface of each finger to improve the quality of electrical connection, this roughening can cause undue abrasion and damage to the pad surfaces. Yet a further disadvantage of the contact fingers shown in both Evans and Higgins is that such fingers are subject to fatigue and failure after a relatively low number of "touchdowns" or duty cycles due to repeated bending and stressing.

Referring to FIG. 1, Cascade Microtech, Inc. of Beaverton, Oregon has developed a probe head 40 for mounting a membrane probing assembly 42. In order to measure the electrical performance of a particular die area 44 included on the silicon wafer 46, the high-speed digital lines 48 and/or shielded transmission lines 50 of the probe head are connected to the input/output ports of the test instrumentation by a suitable cable assembly, and the chuck 51 which supports the wafer is moved in mutually perpendicular X,Y,Z directions in order to bring the pads of the die area into pressing engagement with the contacts included on the lower contacting portion of the membrane probing assembly.

The probe head 40 includes a probe card 52 on which the data/signal lines 48 and 50 are arranged. Referring to FIGS. 2-3, the membrane probing assembly 42 includes a support element 54 formed of incompressible material such as a hard polymer. This element is detachably connected to the upper side of the probe card by four Allen screws 56 and corresponding nuts 58 (each screw passes through a respective attachment arm 60 of

the support element, and a separate backing element 62 evenly distributes the clamping pressure of the screws over the entire back side of the supporting element). In accordance with this detachable connection, different  
 5 probing assemblies having different contact arrangements can be quickly substituted for each other as needed for probing different devices.

Referring to FIGS. 3-4, the support element 54 includes a rearward base portion 64 to which the attach-  
 10 ment arms 60 are integrally joined. Also included on the support element 54 is a forward support or plunger 66 that projects outwardly from the flat base portion. This forward support has angled sides 68 that converge toward a flat support surface 70<sup>80</sup> so as to give the forward  
 15 support the shape of a truncated pyramid. Referring also to FIG. 2, a flexible membrane assembly 72 is attached to the support after being aligned by means of alignment pins 74 included on the base portion. This flexible membrane assembly is formed by one or more plies of insu-  
 20 lative sheeting such as KAPTON™ sold by E.I. Du Pont de Nemours or other polyimide film, and flexible conductive layers or strips are provided between or on these plies to form the data/signal lines 76.

When the support element 54 is mounted on the  
 25 upper side of the probe card 52 as shown in FIG. 3, the forward support 66 protrudes through a central opening 78 in the probe card so as to present the contacts which are arranged on a central region 80 of the flexible membrane assembly in suitable position for pressing engagement  
 30 with the pads of the device under test. Referring to FIG. 2, the membrane assembly includes radially extending arm segments 82 that are separated by inwardly curving edges 84 that give the assembly the shape of a formee cross, and these segments extend in an inclined manner  
 35 along the angled sides 68 thereby clearing any upright components surrounding the pads. A series of contact pads 86 terminate the data/signal lines 76 so that when

the support element is mounted, these pads electrically engage corresponding termination pads provided on the upper side of the probe card so that the data/signal lines 48 on the probe card are electrically connected to the contacts on the central region.

A feature of the probing assembly 42 is its capability for probing a somewhat dense arrangement of contact pads over a large number of contact cycles in a manner that provides generally reliable electrical connection between the contacts and pads in each cycle despite oxide buildup on the pads. This capability is a function of the construction of the support element 54, the flexible membrane assembly 72 and their manner of interconnection. In particular, the membrane assembly is so constructed and connected to the support element that the contacts on the membrane assembly preferably wipe or scrub, in a locally controlled manner, laterally across the pads when brought into pressing engagement with these pads. The preferred mechanism for producing this scrubbing action is described in connection with the construction and interconnection of a preferred membrane assembly 72a as best depicted in FIGS. 6 and 7a-7b.

FIG. 6 shows an enlarged view of the central region 80a of the membrane assembly 72a. In this embodiment, the contacts 88 are arranged in a square-like pattern suitable for engagement with a square-like arrangement of pads. Referring also to FIG. 7a, which represents a sectional view taken along lines 7a-7a in FIG. 6, each contact comprises a relatively thick rigid beam 90 at one end of which is formed a rigid contact bump 92. The contact bump includes thereon a contacting portion 93 which comprises a nub of rhodium fused to the contact bump. Using electroplating, each beam is formed in an overlapping connection with the end of a flexible conductive trace 76a to form a joint therewith. This conductive trace in conjunction with a back-plane conductive layer 94 effectively provides a controlled impedance

data/signal line to the contact because its dimensions are established using a photolithographic process. The backplane layer preferably includes openings therein to assist, for example, with gas venting during fabrication.

5           The membrane assembly is interconnected to the flat support surface 70 by an interposed elastomeric layer 98, which layer is coextensive with the support surface and can be formed by a silicone rubber compound such as ELMER'S STICK-ALL™ made by the Borden Company or  
10 Sylgard 182 by Dow Corning Corporation. This compound can be conveniently applied in a paste-like phase which hardens as it sets. The flat support surface, as previously mentioned, is made of incompressible material and is preferably a hard dielectric such as polysulfone or  
15 glass.

          In accordance with the above-described construction, when one of the contacts 88 is brought into pressing engagement with a respective pad 100, as indicated in FIG. 7b, the resulting off-center force on the  
20 rigid beam 90 and bump 92 structure causes the beam to pivot or tilt against the elastic recovery force provided by the elastomeric pad 98. This tilting motion is localized in the sense that a forward portion 102 of the beam moves a greater distance toward the flat support surface  
25 70 than a rearward portion 104 of the same beam. The effect is such as to drive the contact into lateral scrubbing movement across the pad as is indicated in FIG. 7b with a dashed-line and solid-line representation showing the beginning and ending positions, respectively,  
30 of the contact on the pad. In this fashion, the insulative oxide buildup on each pad is removed so as to ensure adequate contact-to-pad electrical connections.

          FIG. 8 shows, in dashed line view, the relative positions of the contact 88 and pad 100 at the moment of  
35 initial engagement or touchdown and, in solid-line view, these same elements after "overtravel" of the pad by a distance 106 in a vertical direction directly toward the

11  
flat support surface 70. As indicated, the distance 108  
of lateral scrubbing movement is directly dependent on  
the vertical deflection of the contact 88 or, equiva-  
lently, on the overtravel distance 106 moved by the pad  
100. Hence, since the overtravel distance for each  
contact on the central region 80a will be substantially  
the same (with differences arising from variations in  
contact height), the distance of lateral scrubbing move-  
ment by each contact on the central region will be  
substantially uniform and will not, in particular, be  
affected by the relative position of each contact on the  
central region.

Because the elastomeric layer 98 is backed by  
the incompressible support surface 70, the elastomeric  
layer exerts a recovery force on each tilting beam 90 and  
thus each contact 93 to maintain contact-to-pad pressure  
during scrubbing. At the same time, the elastomeric  
layer accommodates some height variations between the  
respective contacts. Thus, referring to FIG 9a, when a  
relatively shorter contact 88a is situated between an  
immediately adjacent pair of relatively taller contacts  
88b and these taller contacts are brought into engagement  
with their respective pads, then, as indicated in  
FIG. 9b, deformation by the elastomeric layer allows the  
smaller contact to be brought into engagement with its  
pad after some further overtravel by the pads. It will  
be noted, in this example, that the tilting action of  
each contact is locally controlled, and the larger  
contacts are able, in particular, to tilt independently  
of the smaller contact so that the smaller contact is not  
urged into lateral movement until it has actually touched  
down on its pad.

Referring to FIGS. 10 and 11, the  
electroplating process to construct such a beam struc-  
ture, as schematically shown in FIG. 8, includes the  
incompressible material 68 defining the support surface  
70 and the substrate material attached thereon, such as

the elastomeric layer 98. Using a flex circuit construction technique, the flexible conductive trace 76a is then patterned on a sacrificial substrate. Next, a polyimide layer 77 is patterned to cover the entire surface of the sacrificial substrate and of the traces 76a, except for the desired location of the beams 90 on a portion of the traces 76a. The beams 90 are then electroplated within the openings in the polyimide layer 77. Thereafter, a layer of photoresist 79 is patterned on both the surface of the polyimide 77 and beams 90 to leave openings for the desired location of the contact bumps 92. The contact bumps 92 are then electroplated within the openings in the photoresist layer 79. The photoresist layer 79 is removed and a thicker photoresist layer 81 is patterned to cover the exposed surfaces, except for the desired locations for the contacting portions 93. The contacting portions 93 are then electroplated within the openings in the photoresist layer 81. The photoresist layer 81 is then removed. The sacrificial substrate layer is removed and the remaining layers are attached to the elastomeric layer 98. The resulting beams 90, contact bumps 92, and contacting portions 93, as more accurately illustrated in FIG. 12, provides the independent tilting and scrubbing functions of the device.

Unfortunately, the aforementioned construction technique results in a structure with many undesirable characteristics.

First, several beams 90, contact bumps 92, and contacting portions 93 (each of which may be referred to as a device) proximate one another results in different localized current densities within the electroplating bath, which in turn results in differences in the heights of many of the beams 90, contact bumps 92, and contacting portions 93. Also, different densities of the ions within the electroplating bath and "random" variations in the electroplating bath also results in differences in

heights of many of the beams 90, contact bumps 92, and contacting portions 93. The different heights of many of the beams 90, contact bumps 92, and contacting portions 93 is compounded three fold in the overall height of many of the devices. Accordingly, many devices will have a significantly different height than other devices. Using membrane probes having variable device height requires more pressure to ensure that all the contacting portions 93 make adequate contact with the test device than would be required if all the devices had equal overall height. For high density membrane probes, such as 2000 or more devices in a small area, the cumulate effect of the additional pressure required for each device may exceed the total force permitted for the probe head and probe station. The excess pressure may also result in bending and breaking of the probe station, the probe head, and/or the membrane probing assembly. In addition, the devices with the greatest height may damage the pads on the test device because of the increased pressure required to make suitable contact for the devices with the lowest height.

Second, the ability to decrease the pitch (spacing) between the devices is limited by the "mushrooming" effect of the electroplating process over the edges of the polyimide 77 and photoresist layers 79 and 81. The "mushrooming" effect is difficult to control and results in a variable width of the beams 90, contact bumps 92, and contacting portions 93. If the height of the beams 90, the contact bumps 92, or the contacting portions 93 are increased then the "mushrooming" effect generally increases, thus increasing the width of the respective portion. The increased width of one part generally results in a wider overall device which in turn increases the minimum spacing between contacting portions 93. Alternatively, decreasing the height of the beams 90, the contact bumps 92, or the contacting portions 93 generally decreases the width of the "mushrooming" effect which in turn decreases the minimum spacing between

contacting portions 93. However, if the height of the contacting portions 93 relative to the respective beam 90 is sufficiently reduced, then during use the rearward end of the beam 90 may sufficiently tilt and contact the test device in an acceptable location, i.e., off the contact pad.

Third, it is difficult to plate a second metal layer directly on top of a first metal layer, such as contacting portions 93 on the contact bumps 92, especially when using nickel. To provide a bond between the contact bumps 92 and the contacting portions 93, an interface seed layer such as copper or gold is used to make an improved interconnection. Unfortunately, the interface seed layer reduces the lateral strength of the device due to the lower shear strength of the interface layer.

Fourth, applying a photoresist layer over a non-uniform surface tends to be semi-conformal in nature resulting in a non-uniform thicknesses of the photoresist material itself. Referring to FIG. 13, the photoresist layer 79 (and 81) over the raised portions of the beams 90 tends to be thicker than the photoresist layer 79 (and 81) over the lower portions of the polyimide 77. In addition, the thickness of the photoresist 79 (and 81) tends to vary depending on the density of the beams 90. Accordingly, regions of the membrane probe that have a denser spacing of devices, the photoresist layer 79 (and 81) will be thicker on average than regions of the membrane probe that have a less dense spacing of devices. During the exposing and etching processing of the photoresist layer 79 (and 81), the duration of the process depends on the thickness of the photoresist 79 (or 81). With variable photoresist thickness it is difficult to properly process the photoresist to provide uniform openings. Moreover, the thinner regions of photoresist layer 79 (or 81) will tend to be overexposed resulting in variably sized openings. Also, the greater the

photoresist layer thickness 79 (or 81) the greater the variability in its thickness. Accordingly, the use of photoresist presents many processing problems.

Fifth, separate alignment processes are  
5 necessary to align the beams 90 on the traces 76a, the contact bumps 92 on the beams 90, and the contacting portions 93 on the contact bumps 92. Each alignment process has inherent variations that must be accounted for in sizing each part. The minimum size of the  
10 contacting portions 93 is defined primarily by the lateral strength requirements and the maximum allowable current density therein. The minimum size of the contacting portions 93, accounting for the tolerances in alignment, in turn defines the minimum size of the contact bumps 92 so that the contacting portions 93 are  
15 definitely constructed on the contact bumps 92. The minimum size of the contact bumps 92, in view of the contacting portions 93 and accounting for the tolerances in alignment, defines the minimum size of the beams 90 so  
20 that the contact bumps 92 are definitely constructed on the beams 90. Accordingly, the summation of the tolerances of the contact bumps 92 and the contacting portions 93, together with a minimum size of the contacting portions 93, defines the minimum device size, and thus  
25 defines the minimum pitch between contact pads.

What is desired, therefore, is a membrane probe construction technique and structure that results in a more uniform device height, decreased spacing between devices, maximized lateral strength, desired geometrics,  
30 and proper alignment.

#### SUMMARY OF THE INVENTION

The present invention overcomes the  
aforementioned drawbacks of the prior art by providing a  
35 substrate, preferably constructed of a ductile material. A tool having the desired shape of the resulting device for contacting contact pads on a test device is brought

into contact with the substrate. The tool is preferably constructed of a material that is harder than the substrate so that a depression can be readily made therein. A dielectric (insulative) layer, that is  
5 / preferably patterned, is supported by the substrate. A conductive material is located within the depressions and then preferably planarized to remove excess from the top surface of the dielectric layer and to provide a flat overall surface. A trace is patterned on the dielectric  
10 layer and the conductive material. A polyimide layer is then preferably patterned over the entire surface. The substrate is then removed by any suitable process.

The foregoing and other objectives, features, and advantages of the invention will be more readily  
15 understood upon consideration of the following detailed description of the invention, taken in conjunction with the accompanying drawings.

#### BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWINGS

20 FIG. 1 is a perspective view of a membrane probing assembly bolted to a probe head and a wafer supported on a chuck in suitable position for probing by this assembly.

FIG. 2 is a bottom elevational view showing  
25 various parts of the probing assembly of FIG. 1, including a support element and flexible membrane assembly, and a fragmentary view of a probe card having data/signal lines connected with corresponding lines on the membrane assembly.

30 FIG. 3 is a side elevational view of the membrane probing assembly of FIG. 1 where a portion of the membrane assembly has been cut away to expose hidden portions of the support element.

FIG. 4 is a top elevational view of an  
35 exemplary support element.

FIGS. 5a-5b are schematic side elevational views illustrating how the support element and membrane

assembly are capable of tilting to match the orientation of the device under test.

FIG. 6 is an enlarged top elevational view of the central region of the construction of the membrane assembly of FIG. 2.

FIGS. 7a-7b are sectional views taken along lines 7a-7a in FIG. 6 first showing a contact before touchdown and then showing the same contact after touchdown and scrub movement across its respective pad.

FIG. 8 is a schematic side view showing, in dashed-line representation, the contact of FIGS. 7a-7b at the moment of initial touchdown and, in solid-line representation, the same contact after further vertical overtravel by the pad.

FIGS. 9a and 9b illustrate the deformation of the elastomeric layer to bring the contacts into contact with its pad.

FIG. 10 is a longitudinal sectional view of the device of FIG. 8.

FIG. 11 is a cross sectional view of the device of FIG. 8.

FIG. 12 is a more accurate pictorial view of the device shown in FIGS. 10 and 11.

FIG. 13 is a detailed view of the device shown in FIG. 11 illustrating the uneven layers that result during processing.

FIG. 14 is a pictorial view of a substrate.

FIG. 15 is a pictorial view of an exemplary embodiment of a tool, and in particular a dimpling tool, of the present invention.

FIG. 16 is a pictorial view illustrating the tool of FIG. 15 coming into contact with the substrate of FIG. 14.

FIG. 17 is a pictorial view of the substrate of FIG. 14 after the tool of FIG. 15 has come into contact therewith.

FIG. 18 is a sectional view of the substrate of FIG. 14 with a polyimide layer supported thereon.

FIG. 19 is a pictorial view of the tool of FIG. 16 together with a z-axis stop.

5 FIG. 20 is a sectional view of the substrate of FIG. 14 with a trace, conductive material in the depression, and additional polyimide layer thereon.

FIG. 21 is a pictorial view of the device of FIG. 20, inverted, with the substrate removed.

10 FIG. 22 is a breakaway sectional view of the contacting portion of FIG. 21.

FIG. 23 is a schematic view illustrating one arrangement of the devices of the present invention.

*Present not*  
15 FIG. 24 is a schematic view illustrating the contact of a traditional contacting portion and the oxide layer of a solder bump.

FIG. 25 is a plan view of an alternative device with an elongate probing portion.

20 FIG. 26 is a side view of the device of FIG. 25 with an elongate probing portion.

FIG. 27 is a pictorial view of a solder bump with a mark therein as a result of the device of FIGS. 25 and 26.

25 FIG. 28 is a pictorial view of another alternative probing device.

FIG. 29 is a pictorial view of a further alternative probing device suitable for solder bumps.

30 FIG. 30 is a side view of a true Kelvin connection using the devices of the present invention.

#### DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

The currently employed construction techniques for membrane probes involves starting with the flat rigid substrate to support additional layers fabricated thereon. To decrease the pitch and provide devices with increased uniformity requires increasingly more complex and expensive processing techniques. In direct contrast

to the current techniques of constructing layers from the "bottom up" upon a supporting substrate, the present inventors came to the realization that by using a suitable tool a substrate may be coined to create the desired beams, contact bumps, and contacting portions. The remaining layers are then constructed "top down" on the beam. The substrate itself is thereafter removed.

Referring to FIG. 14, a substrate 200 is preferably constructed from a ductile material such as aluminum, copper, lead, indium, brass, gold, silver, platinum, or tantalum, with a thickness preferably between 10 mills and 1/8 inch. The top surface 202 of the substrate 200 is preferably planar and polished for optical clarity to improve viewing, as described later.

Referring to FIG. 15, a tool and in particular a "dimpling" tool 210 is constructed with a head 212 having the desired shape of the resulting device for contacting the contact pads on the test device. The dimpling tool 210 includes a projection 214 to connect to a dimpling machine (not shown). The tool 210 is supported by the dimpling machine with the head 212 oriented to come into contact with the top surface 202 of the substrate 200. The tool 210 is preferably constructed of a material that is harder than the substrate 200, so that a dimple can be readily made therein. Suitable material for the tool 210 is, for example, tool steel, carbide, chromium, and diamond. The preferred dimpling machine is a probe station which has accurate x, y, and z control. It is to be understood that any other suitable dimpling machine may likewise be used. Referring to FIG. 16, the tool 210 is pressed into contact with the top surface 202 of the substrate 200 resulting in a depression 216 matching the shape of the tool 210 upon its removal from the substrate 200, as shown in FIG. 17. The tool 210 is used to create a plurality of depressions 216 in the substrate 200 matching the desired pattern, such as the pattern shown in FIG. 6. Conversely, the tool 210 can be held

but shown in FIG. 16, 17

stationary and the substrate 200 can be moved in the z-direction until the top surface 202 of the substrate is pressed into contact with the tool 210 resulting in the same depression 216 matching the shape of the tool 210 upon its removal from the substrate 200, as shown in FIG. 17.

Referring to FIG. 18, a polyimide layer 220 is patterned around the depressions 216. It is to be understood that any other suitable insulative layer or dielectric layer may likewise be used. In the process of patterning the polyimide layer 220, it is somewhat difficult to remove the polyimide from the depressions 216 during the exposing and etching process for the polyimide layer 220. This is especially true when the depressions 216 are relatively deep with steeply inclined sides. Alternatively, the polyimide layer 220 may be patterned on the top surface 202 of the substrate 200 with openings located therein where the depressions 216 are desired. Thereafter, the tool 210 is used to create the depressions 216 in the substrate 200 through the openings provided in the polyimide layer 220. This alternative technique eliminates the difficult process of adequately removing the polyimide layer 220 from the depressions 216.

It is expensive to manufacture masks for exposing the polyimide layer 220 that have tolerances sufficient to precisely align the openings for the depressions 216. The tool 210, in combination with the dimpling machine, can be aligned to the actual location of one of the openings that results from exposing and etching the polyimide layer 220 with a relatively inexpensive, and somewhat inaccurate mask. The present inventors came to the realization that localized regions of the mask, and thus the openings resulting therefrom, tend to be relatively well aligned for purposes of dimpling. Likewise, regions of the mask distant from one another tend not to be relatively well aligned for

purposes of dimpling. Accordingly, automatically dimpling the substrate 200 to match an anticipated pattern with many depressions 216 distant from one another, with an accurate dimpling machine, will result in the dimpling tool not accurately being aligned with the openings at regions distant from the initial alignment point. To improve the accuracy of the alignment process the present inventors came to the realization that the dimpling machine may be realigned to the actual openings in the polyimide layer 220 at different remote locations, so that each localized region is relatively accurately aligned, while the overall alignment may be somewhat off. In this manner a relatively inexpensive mask may be used.

Preferably the dimpling machine includes accurate z-axis movement so that the depth of each depression is identical, or substantially identical. Referring to FIG. 19, if sufficiently accurate z-axis movement is not available then an alternative dimpling tool 240 with a built in z-axis stop 242 may be used. The z-axis stop 242 is a projection extending outward from the head 244 that comes to rest on the top surface of the polyimide 220 or top surface 202 of the substrate 200. The z-axis stop 242 is positioned with respect to the head 244 such that the proper depth is obtained, taking into account whether or not the polyimide layer 220 is previously patterned before using the dimpling tool 240.

Referring to FIG. 20, a conductive material 250 is electroplated onto the polyimide 220 and substrate 200 thereby filling up the depressions 216 with the conductive material 250, such as nickel and rhodium. It is to be understood that any other suitable technique may be used to locate conductive material within the depressions 216. The conductive material 250 is then preferably lapped to remove excess from the top surface of the polyimide layer 220 and to provide a flat overall

surface. The preferred lapping process is a chemical-mechanical planarization process. A trace 252 is patterned on the polyimide layer 220 and the conductive material 250. The trace 252 is preferably a good conductor such as copper, aluminum, or gold. A polyimide layer 254 is then patterned over the entire surface. Further layers of metal and dielectric may be formed. The substrate 200 is then removed by any suitable process, such as etching with hydrochloric acid (HCL 15%) or sulfuric acid ( $H_2SO_4$ ). Hydrochloric acid and sulfuric acid are not reactive with the polyimide layer 220 nor the conductive material 250, such as nickel or rhodium. It is to be understood that the polyimide layer 254 may alternatively be any suitable insulator or dielectric layer.

Referring to FIG. 21, the contacting portion 260 of the resulting device is preferably selected to have a low contact resistance so that a good electrical connection may be made with the test device. While nickel has a relatively low contact resistance, rhodium has an even lower contact resistance and is more resistant to wear than nickel. Accordingly, the depressions 216 are preferably coated with a layer of rhodium. Using normal processing techniques the thickness of rhodium is limited to approximately 5 microns. The resulting device includes an exterior layer of rhodium, and in particular the contacting portion 260, which is then filled with the remaining conductive material, such as nickel or a nonconductive fill. The conductive material need not fill the entire depression.

The aforementioned "top-down" construction process provides numerous advantages over the traditional "bottom-up" processing technique of constructing layers upon a supporting substrate. These advantages also permit the capability of constructing devices with improved characteristics.

First, there are no limitations to the height of the resulting devices which were previously imposed by limitations of photoresist processing. The ability to construct devices having any suitable height also  
5 relieves the limitations imposed by attempting to electroplate into a tall narrow openings in photoresist, which is difficult.

Second, the elevation of the contacting portions 260 of the devices is extremely uniform because  
10 it is defined solely by the tooling process, which is mechanical in nature. Different localized current densities of the electroplating bath, different densities of the ions within the electroplating bath, and "random" variations in the electroplating bath are eliminated from  
15 impacting the overall shape and height of the resulting devices. With substantially uniform elevation of the devices, less force is required for the devices to make adequate contact with the test device which, in turn, decreases the likelihood of bending and breaking the  
20 probe station, the probe head, and/or the membrane probing assembly. Also, the substantially uniform elevation of the devices decreases the likelihood of damaging contact pads on the test device with excessive pressure.

Third, the contacting portion 260 of the  
25 devices are stronger because the device is constructed of a single homogenous material during one depositing process requiring no interfacial layers, as previously required for the multiple processing steps. This permits reducing the size of the contacting portions to the  
30 limitation of the maximum current density allowable therein during testing and not the minimum shear force of the interfacial layers.

Fourth, the shape of the resulting devices are customizable to effectively probe different materials.  
35 The shape of the device may have steep sidewall angles, such as 85 degrees, while still providing mechanical strength, stability, and integrity. The steep sidewalls

permit narrower devices to be constructed which allows for a greater density of devices for increasingly denser arrangements of contact pads on the test device. Moreover, the angle of the sidewalls are not dependent (e.g. independent) on the crystalline structure of the substrate.

Fifth, the shape of the contacting portion is known precisely, and is uniform between devices, which permits uniform contact with the contact pads of the test device.

Sixth, the alignment of the different portions of the resulting device are exactly uniform between devices because each device was constructed using the same tooling process. With exact alignment of the lower portions of each device (beam and contact bump) in relation to the contacting portion, there is no need to provide additional leeway to accommodate processing variations inherent in photoresist processes and in electroplating processes. Also, the "mushrooming" effect of the electroplating process is eliminated which also reduces the required size of the device. The alignment variability reduction, and virtual elimination, of different devices 300 allows a significantly decreased pitch to be obtained, suitable for contact pads on the test device that have increased density.

Seventh, the shape of the resulting devices may be tailor shaped to provide optimal mechanical performance. To provide the scrubbing function, as described in the background portion, the device should have a beam and bump structure that tilts upon contact. The device 300 may include an inclined surface 304 between its tail 302 and the contacting portion 260. The inclined surface 304 provides for increased strength along portions of the length of the device 300 which permits the tail 302 to be thinner than its head 306. The torque forces applied to the device 300 during the tilting process of the device 300 tend to decrease over the length of the device 300

which has a correspondingly thinner material defined by the inclined surface 304. With a thinner tail 302 and material proximate the tail 302, the tail 302 of the device 300 has less likelihood of impacting the test device if excess tiling occurs. The improved shape of the device 300 also decreases the amount of metal material required.

Eighth, "look-up" cameras are used to obtain an image of the lower portion of the membrane probe to determine the precise location of the devices 300 relative to the contact pads on the test device. Using "look-up" cameras permits automatic alignment of the membrane devices relative to the contact pads so that automatic testing may be performed. In order to obtain an image of the devices 300 on the membrane probe the "look-up" cameras normally utilize light to illuminate the devices 300. Unfortunately, the traditional planar processing techniques result in relatively flat surfaces on the beams, contact bumps, and contacting portions, in a perpendicular orientation to the "look up" cameras each of which reflects light back to the "look-up" camera. The light reflecting back to the "look up" camera from all the surfaces frequently results in some confusion regarding the exact location of the contacting portions 260. The inclined surface 304 of the devices 300 tends to reflect incident light away from lowerly disposed "look-up" cameras, while the contacting portions 306 tend to reflect incident light back to lowerly disposed "look-up" cameras. Light returning to the "look-up" camera primarily from the contacting portions 306 results in less potential confusion regarding the exact location of the contacting portions.

Ninth, the initial polishing of the top surface 202 of the substrate 200 results in a matching smooth lower surface for the polyimide layer 220 patterned thereon. After etching away, or otherwise removing, the substrate 200 the lower surface of the polyimide layer

Fourth, referring to FIG. 23, a triangular shape of the footprint of the device allows for high lateral stability of the devices while permitting a decrease in the pitch between devices. The contacting portions 403 of the device are preferably aligned in a linear arrangement for many contact pads of test devices. The triangular portions of the device are aligned in alternatively opposing directions.

Fifth, the capability of constructing contacting portions that are raised high from the lower surface of the device, while still maintaining uniformity in the device height and structural strength, allows the device to provide scrubbing action while the lower surface of the device requires little movement. The small movement of the lower surface of the device to make good electrical contact during testing decreases the stress on the layers under the lower surface of the device. Accordingly, the likelihood of cracking the polyimide layers and the conductive traces is reduced.

When probing an oxide layer on solder bumps, or solder balls on wafers that are to be used with "flip-chip" packaging technology, such as the solder bumps on the printed circuit boards, the oxide layer developed thereon is difficult to effectively penetrate. Referring to FIG. 24, when contacting a traditional contacting portion of a membrane probe onto the solder bump, the oxide 285 tends to be pressed into the solder bump 287 together with the contacting portion 289 resulting in a poor interconnection. When using conventional needle probes on solder bumps, the needles tend to skate on the solder bumps, bend under within the solder bumps, collect debris on the needles, flake the debris onto the surface of the test device, and cleaning the needle probes is time consuming and tedious. Moreover, needle probes leave non-uniform probe marks on the solder bumps. When probing solder bumps used on flip-chips, the probe marks left in the upper portion of the solder bump tends

to trap flux therein, which when heated tends to explode, which degrades, or otherwise destroys, the interconnection. Referring to FIGS. 25 and 26, an improved device construction suitable for probing solder bumps is shown.

5 The upper portion of the device includes a pair of steeply inclined sides 291 and 293, such as 15 degrees off vertical, with preferably polished sides. The inclined sides 291 and 293 preferably form a sharp ridge 295 at the top thereof. The angle of the sides 291 and  
10 293 is selected with regard to the coefficient of friction between the sides and the oxide on the solder bump, so that the oxide coated surface tends to primarily slide along the surfaces of the sides 291 and 293, or otherwise shear away, and not be significantly carried on  
15 the sides as the device penetrates a solder bump. Referring to FIG. 27, the substantially sharp ridge also provides for a mark (detent) after contact that extends across the entire solder bump. Subsequent heating of the solder bumps, together with flux, result in the flux  
20 exiting from the sides of the solder bump thereby avoiding the possibility of explosion. In addition, the resulting mark left on the solder bumps is uniform in nature which allows manufacturers of the solder bumps to account for the resulting marks in their design. Also,  
25 less force is required to be applied to the device because it tends to slice through the solder bump rather than make pressing contact with the solder bump. The flatter surface 405 prevents slicing too deeply into the solder ball (bump).

30 Referring to FIG. 28, to provide a larger contact area for testing solder bumps a waffle pattern may be used.

Referring to FIG. 29, an alternative device includes a pair of projections 311 and 313 that are  
35 preferably at the ends of an arch 315. The spacing between the projections 311 and 313 is preferably less than the diameter of the solder bump 317 to be tested.
